Submitted 4 August 2011; accepted in final form 13 October 2012

The 100-electrode Utah Slanted Electrode Array (USEA) provides a prime candidate for restoring hand function in paralyzed patients by activating motor fibers, and may ameliorate some of the challenges associated with full-muscle FES or extraneural stimulation. The USEA electrodes are arranged in a 10 × 10 configuration, spaced at 400-μm intervals, with electrode lengths ranging from 0.5 to 1.5 mm (Branner and Normann 2000), thereby providing relatively complete coverage of a nerve. Because the electrodes penetrate directly into the nerve fascicles, their tips closely abut different populations of motor or sensory axons, allowing multiple, selective sites for stimulation or recording. The USEA has been used previously to activate cat hindlimb muscles selectively, independently, and in a fatigue-resistant manner via interleaved activation of multiple different motor units for a single muscle, each at a relatively low frequency (Frankel et al. 2011; McDonnall et al. 2004). Thus intrafascicular nerve stimulation with USEAs may also provide an improved level of hand movements, compared with conventional FES. Among other advantages, a USEA may access multiple muscles with a single implant site and independent access to multiple different motor units within the same muscle, thereby also allowing more graded force control and more fatigue-resistant movements via interleaved stimulation (Normann et al. 2012). It may also allow access to intrinsic hand muscles, which is difficult to achieve with conventional extraneural nerve stimulation. Finally, intrafascicular electrodes, such as those of the USEA, can also record single-unit action potentials, opening the possibility of detecting afferent signals from sensory receptors in intact limbs distal to the neural disruption (Branner et al. 2004).

Similarly, amputees also could benefit from the selective stimulation and recording capabilities of intrafascicular electrodes, which would allow the patients’ nervous system to communicate with computer-controlled prostheses such as robotic hands or knees. In this instance, implanted electrodes would be used to record from efferent motor fibers to obtain motor command signals and to activate small populations of sensory afferents in order to restore discrete sensations. However, the electrodes’ functionality with respect to selective stimulation and recording would remain the same.

Previous studies have shown that, at a gross level, motor fibers do cluster according to their function (Gustafson et al. 2009), and some motor fibers may be part of more than one

nerve (Badia et al. 2010). However, these studies do not address the relationship between the sensory and motor fibers within a single fascicle, and it remains unclear whether fibers innervating a given body region tend to cluster together, or whether the nerve fibers organize separately into sensory and motor bundles within the fascicle.

The human hand is a complex mechanical system with 27 degrees of freedom that is difficult to emulate. Monkeys have opposable thumbs, independent finger control (Schieber 1991), and intrinsic and extrinsic muscles controlling the hand and arm similar in number to those in humans (Liu et al. 1996). Monkeys thus provide an attractive model for testing the ability of the USEA to restore human hand function. The muscles used for generating power grip and precision grip are innervated by the median, ulnar, and radial nerves in both humans and monkeys. Selective activation of monkey hand muscles has also been reported with the use of flat interface nerve electrodes (FINEs) (Brill et al. 2009).

In the present study, we examined the feasibility and potential advantages of USEAs for activation of motor and sensory fibers in the median, radial, and ulnar nerves of nonhuman primates, using acute, anesthetized preparations. Although the commercial version of a single Utah Electrode Array (UEA) (with equal-length electrodes) has been previously implanted in the median nerve of one human subject with success (Warwick et al. 2003), the data set from that study was limited. Aside from that somewhat anecdotal report, there have been no previous investigations of USEAs in nonhuman primates, or in any of the forelimb nerves of any species. Here we examined the ability of different USEA electrodes to provide access to different extrinsic and intrinsic hand muscles and the selectivity of that activation. We also examined the ability to activate multiple motor groups via multiple nerves so as to achieve coordinated gripping sequences that could restore clinically useful hand movements after paralysis. In addition to motor responses, we examined stimulation-evoked responses centered around primary somatosensory cortex that could be useful for restoration of cutaneous and proprioceptive sensation in amputees. Finally, the combination of sensory and motor responses was examined to determine whether fibers from a single body region lie together, or whether the nerve fibers organize separately into sensory and motor regions within the fascicle.

MATERIALS AND METHODS

Surgery

These experiments were performed in nonrecovery surgical procedures on four monkeys that were being euthanized after a series of unrelated studies. All procedures were performed under deep surgical levels of anesthesia, with isoflurane gas anesthetic after premedication with buprenorphine, as approved by the Institutional Animal Care and Use Committee of Northwestern University. Experiments lasted ~30 h. Differences in procedures across animals are summarized in Table 1.

to the cortex were confirmed posthumously. In the fourth monkey, a craniotomy was performed, and an electrocorticography (ECoG) grid was placed over somatosensory cortex and adjacent cortices.

Electromyography Recording

Fine-wire electromyography (EMG) electrodes were placed in forearm, finger, and wrist muscles, and electrical potentials were recorded on a Cerebus recording system (Blackrock, Salt Lake City, UT) at 10,000 samples/s with a low-pass filter at 7.5 kHz. Bipolar recordings were made with intramuscular electrodes inserted into each muscle, including, in some cases, separate compartments in a single muscle. In all experiments, the main muscles used in grasp were monitored, including flexor carpi radialis (FCR), flexor digitorum superficialis (FDS), flexor carpi ulnaris (FCU), medial head of flexor digitorum profundus (FDPm), ulnar head of flexor digitorum profundus (FDPu), flexor pollicis brevis (FPB), brachioradialis, extensor carpi radialis (ECR), extensor digitorum communis (EDC), extensor carpi ulnaris (ECU), pronator teres (PT), flexor digitorum profundus (FDP), the dorsal interosseus, and lumbricales. In some monkeys additional electrodes were inserted in triceps lateralis, triceps longus, abductor pollicis brevis (AdP), and palmaris longus. Additionally, separate compartments in EDC and ECR were monitored in two monkeys.

Nerve Exposure

Nerves in the arm were exposed at the elbow and shoulder for subsequent implantation of USEAs. The median nerve was exposed through a longitudinal incision from midhumeral level to beyond the antecubital fossa. The PT muscle and the brachioradialis muscle were reflected in order to dissect the median nerve free just proximal to its branch point in the proximal forearm. To gain access to the ulnar nerve the medial antecubital cutaneous nerve was transected at the elbow, and the ulnar nerve was dissected free just proximal to the elbow. The radial nerve was exposed from the volar side of the arm by continuing the dissection of the muscles deep to median and ulnar nerves. Alternatively, the radial nerve was exposed via a second incision on the dorsal aspect of the arm between the brachioradialis and extensor carpi radialis longus (ECRL) muscles, exposing the radial nerve just proximal to its branch points to the brachioradialis and forearm extensor muscles.

All three nerves were also exposed at the brachial plexus to allow implantation of USEAs at a second location in each nerve and to examine the effectiveness of different implant locations. The incision in the arm was extended proximally, and, in order to fully expose the nerves of the brachial plexus, the pectoralis minor and pectoralis major muscles were incised and retracted.

USEA Implantation

USEAs were implanted in nerves just distal to the brachial plexus (Fig. 1A) and near the elbow (Fig. 1B) by means of a high-speed insertion system (Rousche and Normann 1992). Arrays were connected to stimulation and recording systems via a modified Integrated Cable Systems (ICS Mfg., Longmont, CO) or a Tucker-Davis Technologies (TDT, Alachua, FL) 96-pin connector and adapter board.
Electrode at a specific nEMG value, by use of the following formula to produce a normalized EMG value (nEMG).

Values for each run were divided by the maximum evoked EMG to normalize EMG values. Single- or multi-electrode stimulation through the USEA. The EMG response curve that had also been used for muscle activation. For USEA electrodes that could drive cortical activity, we then determined which muscle responded most strongly to that electrode. Finally, for each ECoG electrode, we averaged the correlations across different USEA electrodes that had activated each muscle to determine the mean correlation between muscles activated by USEA electrodes and somatosensory cortical response location.

**RESULTS**

**General Results**

Implants in all nerves across all implant levels were capable of evoking muscle contractions in nerve-appropriate muscles that were detectable through EMG or visual inspection. Currents to evoke these contractions were not directly measured (given the use of constant-voltage stimulation at 3 V) but lie below levels that could damage tissue with short-term stimulation sessions, between 5 and 50 μA, as documented in the cat, including for short-term stimulation across multiple sessions (Branner et al. 2004; Frankel et al. 2011; Normann et al. 2012).

**Single-Pulse, Single-Electrode Stimulation: Muscle Activation and Selectivity**

Recruitment curves. We first examined the ability to recruit responses in individual muscles by delivering single-pulse stimulation through individual USEA electrodes (typically using a series of varying stimulus-pulse durations) while measuring the evoked EMG responses. As in previous work, the muscle responses to USEA stimulation were graded across the range of pulse widths; perithreshold pulse widths had a mean of 15.4 ± 0.5 μs. Calculated SI values indicated that single-electrode, single-pulse intrafascicular nerve stimulation could often activate individual extrinsic muscles to functionally useful levels without activating other muscles (Fig. 2A) and that
generated, the mean SI across all implants at 0.2 nEMG was 0.44, and the mean SI across all implants at 0.5 nEMG was 0.2. In the three monkeys in which input-output curves were provided, selectivity tended to be higher at the elbow than at the shoulder, whereas in the ulnar nerve selectivity at the elbow tended to be lower than at the shoulder (0.26 ± 0.02 vs. 0.78 ± 0.05; 84 and 20 electrodes, 2 and 1 arrays, respectively) showed that selectivity tended to be higher at the elbow than at the shoulder, whereas in the ulnar nerve selectivity at the elbow tended to be lower than at the shoulder (0.26 ± 0.02 vs. 0.78 ± 0.05; 84 and 20 electrodes, 2 and 1 arrays, respectively). Multiple-comparison tests with a Scheffé correction indicated that SI was statistically different across all nerve pairings (all P < 0.05), with population-normalized-mean values as follows: median 0.56 ± 0.02, ulnar 0.44 ± 0.03, and radial 0.36 ± 0.02.

Musculotopic arrangement of nerve fibers. To evaluate the musculotopic arrangement of motor fibers within a nerve, we examined the extent to which neighboring USEA electrodes evoked responses in a common muscle. For all implants, electrode sites that recruited the same muscle or close synergist muscles were usually in close proximity to one another, suggesting a musculotopic arrangement (Fig. 2B). To quantify musculotopy, for each USEA electrode we first calculated the expected number of neighboring (adjacent) electrodes that would activate the same muscle if nerve fibers were randomly distributed, based on the number of responses evoked in each muscle for each given USEA. We then compared the number expected from chance with the number of neighboring electrodes that had actually recruited the same response as the given test electrode at threshold. Significantly more neighboring electrodes recruited the same motor response than expected from chance alone (mean = 0.98 ± 0.07 electrodes, P < 0.05) (Fig. 4), indicating that motor fibers were organized musculotopically within all nerves.

Single-Electrode Pulse Trains Also Recruited Selective Movements

Functionally useful movements require stimulus trains, rather than single-pulse activation of motor nerve fibers. To test our ability to generate individuated and coordinated movements with the USEA, we applied pulse trains (30–50 Hz, 1.8–3 V) to particular electrodes. Pulse widths used in the functional muscle contraction sequences were higher than perithreshold values. We monitored movements at the hand, elbow, and shoulder, as well as rotation of the forearm. Motions were observed and categorized in terms of the joint at which the movement occurred and its direction, together with the muscles that showed EMG activity. Across all subjects, median nerve stimulation generated six to nine visually different movements across different combinations of joints (Fig. 5 and Supplemental Movie S1).1 These

1 Supplemental Material for this article is available online at the Journal website.
movements approximately corresponded to the activation of individual muscles associated with each movement in various combinations (e.g., FCR for wrist flexion; FDS and FDP for finger flexion; the intrinsic muscles and FPB for small finger and thumb movements; and PrT for arm pronation). The ability of the different USEA electrodes to elicit distinct movements and different EMG responses indicates that selective stimulation was partially maintained during pulse train delivery, such that even with the low-level activation of additional muscles the motions evoked were clearly related to the muscle that was selectively activated through single-pulse stimulation.

Analysis of variance (ANOVA) of SI, linear model, hierarchical sum of squares. Individual animal and nerve implanted were significant factors. All electrodes capable of eliciting a 0.2 nEMG response or greater were included in the analysis.

Multielectrode, Multi-USEA Pulse Trains Evoked Coordinated Grasp

To produce a coordinated grasp, muscles not only must be selectively activated but also must contract and relax in specific patterns (Long et al. 1970; Maier and Hepp-Reymond 1995). To test the ability to evoke these more complex types of movements, between three and nine electrodes across all arrays were selected that activated the muscles necessary for power grip through the UINTA stimulation system custom software. A 2-s movement sequence was programmed consisting of finger extension to open the hand, finger flexion to grasp an object, and, finally, finger extension to release the object. Activation of extrinsic finger flexors that span the wrist typically caused undesired wrist flexion along with flexion of the fingers. In these cases, wrist extensors were also activated to counteract the flexion force, a combination that is necessary under normal conditions as well. A 50-g ball was placed in the animal’s palm as it was initially opened. When the hand closed, the ball was held within the hand until the program instructed the fingers to extend (Fig. 6 and Supplemental Movie S2). The shown movement was evoked with six electrodes with pulse widths of 10, 100, 10, 50, 100, and 500 μs (average 128 μs). Once programmed, the control sequence reliably produced the desired movement sequence for the duration of the experiment. Via this technique, the anesthetized monkey’s hand also engaged a variation of power grip sometimes called bucket grip. In addition, electrodes associated with intrinsic hand muscles were combined with the extrinsic muscles to generate a pinch grip between the thumb and forefinger (Supplemental Movie S3).

USEA Activation of Sensory Fibers

To examine our ability to evoke sensory signals, as would be necessary in a limb-loss prosthesis that restores sensation, we monitored SSEPs, using either skull screws (n = 3) or an ECoG grid (n = 1) during USEA stimulation. Stimulation produced short-latency (~5 ms to onset) SSEPs in and around primary somatosensory cortex on 52% of tested stimulating electrodes. To avoid the possibility of indirect sensory activation (e.g., H or F reflexes), the analysis of SSEP data was limited to the first 20 ms after stimulation (Fig. 7). The short latency of these responses indicates that they are likely due to direct afferent fiber activation, not indirect sensory responses due to movement caused by concurrent muscle activation. In the monkey with the ECoG grid, low-level stimulation applied to USEAs (n = 3 USEAs) recruited cortical responses at a pulse duration that did not activate muscles in 32% of electrodes, providing further evidence that direct sensory fiber activation was achieved.

Relationship Between Somatotopic and Musculotopic Organizations

We next examined whether afferent nerve fibers were organized somatotopically and the relationship between somatotopic and musculotopic organizations.

Different USEA electrodes evoked different cortical responses. Consistent with a somatotopic organization, different electrodes on the same USEA, or on different USEAs, evoked responses recorded through different cortical electrodes in three monkeys. (Upon postmortem dissection, one primate was found to have a lesion within the somatosensory cortex from previous work that precluded cortical analyses for the present work.) For monkeys with skull screws (n = 2) rather than the ECoG electrode grid, different patterns of cortical activation were discernible only with stimulation via USEAs on different nerves, presumably because of the relatively coarse spatial resolution provided by skull screw recordings. For example, the maximal responses to median nerve stimulation were recorded on electrodes different from the electrodes showing the maximal responses evoked by radial nerve stimulation. Additionally, for the one monkey with the ECoG grid, different USEA electrodes on a single USEA in a given nerve evoked responses in discernibly different cortical regions (i.e., different ECoG electrodes).

Somatotopic and musculotopic maps covary. Results showed that the amplitude of the SSEP on some cortical electrodes was significantly correlated with stimulation strength on USEA ele-

---

Fig. 4. Quantification of musculotopic arrangement of motor fibers. We assessed the musculotopic organization of nerve fibers by comparing the muscle activated by each USEA electrode with the muscles activated by neighboring USEA electrodes. For each electrode capable of activating a muscle, we calculated the probability that a neighboring electrode would activate the same muscle from chance alone. The actual number of neighboring electrodes that preferentially activated the same muscle was consistently higher than the number expected from chance (i.e., the actual − expected difference was >0), indicating a musculotopic arrangement in which motor fibers to a given muscle were close together within the nerve. This pattern held for muscles of all types and each nerve individually.
In addition, adjacent cortical electrodes showed similar correlations, whereas cortical electrodes distant to one another did not. Instead, responses on distal cortical electrodes were correlated with stimulus strength on USEA electrodes that activated other muscles. For example, stimulation strengths on USEA electrodes implanted in the median nerve that activated wrist flexor muscles were correlated (r > 0.45 or greater, P < 0.05) with response magnitudes on ECoG electrode 18, whereas stimulus strengths on USEA electrodes that activated finger flexor muscles were correlated (r > 0.45 or greater) with response magnitudes on ECoG electrodes 1 and 2 (Fig. 8).

These results imply that somatosensory fibers and motor fibers for a given body region travel closely together within the nerve. Given that USEA-evoked motor selectivity appears to hold even at the subfascicular level, it is plausible that the motor-sensory coorganization occurs at the subfascicular level as well. These findings complement earlier work demonstrating that somatosensory fibers of the same submodality and receptive field region cluster together within the nerve (Ekedahl et al. 1997; Hallin 1990).

**DISCUSSION**

**General**

Here we report the first USEA implantation in the peripheral nerves of a nonhuman primate, the first attempt to quantify the efficacy and selectivity of the USEA in activating extrinsic and intrinsic hand muscles, and the first recordings of cortical sensory responses evoked through USEA stimulation of arm nerves. The results here demonstrate that infrafascicular electrodes can provide excellent access to multiple muscles, including intrinsic hand muscles not typically accessed in conventional FES. The different electrodes of a single USEA could activate multiple different muscles, and the combination of just three USEAs in the median, radial, and ulnar nerves could access nearly all forearm and hand muscles. Although the procedure to implant USEAs for clinical applications...
would be invasive, it is less invasive and would require less recovery time than, for example, targeted reinnervation approaches presently used successfully for control of prosthetic limbs (Kuiken et al. 2009).

Recruitment of Motor Responses via USEA Stimulation of Motor Fibers

Activation of motor fibers provided fine-resolution control of forearm movements. Selective activation of the muscles used to grip objects was achieved with both the elbow-level and shoulder-level implants, indicating that both locations have potential uses for peripheral nervous system (PNS)-based prostheses. Although shoulder-level implants had a mean SI comparable to elbow-level implants, the small sample size makes determination of the strength of that trend difficult. However, the greater number of usable electrodes suggests that the elbow may be a more desirable implant location when available. Nonetheless, shoulder-level implants would be useful in cases of high-humeral amputation, or for recruiting muscles of the

**Fig. 8.** Coregistration of musculotopic and somatotopic maps. Different USEA electrodes that evoked responses in a given muscle via activation of motor nerve fibers also evoked responses on the same cortical ECoG electrodes, via activation of sensory nerve fibers. Each grid displays a color map for the 32 ECoG electrodes for a given muscle, indicated by the label above the grid [e.g., brachioradialis (Brd), extensor carpi radialis (ECR), etc.] Each electrode was categorized by muscle, requiring an SI of >0.25 calculated at normalized EMG value (nEMG) of 0.2. Colors correspond to the mean Pearson’s correlation coefficient ($r$) between the stimulus pulse width and the amplitude of the evoked cortical response across all electrodes that could activate each muscle ($n = 692, P < 0.01$ shown). ECoG electrodes within each grid are arbitrarily numbered from 1 to 8 from left to right at bottom, extending through 25–32 at top. USEA electrodes that evoked responses in a given muscle or similar muscles, e.g., wrist extensors, also evoked responses in a similar set of cortical electrodes, whereas USEA electrodes that evoked responses in other muscles activated other cortical areas. For example, USEA electrodes that activated extensor muscles extensor carpi ulnaris (ECU) and ECR also evoked responses on ECoG electrodes 10 and 11, as indicated by the high correlation between the stimulus pulse width and the amplitude of the evoked somatosensory evoked potential (SSEP) on those ECoG electrodes. In contrast, USEA electrodes that activated the flexor muscle FDS evoked responses in more anterior-lateral cortical regions (ECoG electrodes 1 and 2). Muscles are grouped according to their dominant innervation, e.g., radial nerve (top), median nerve (middle 2 rows), and ulnar nerve (bottom).
upper arm after SCI, given that some electrodes at the shoulder level were selective (40 electrodes with an SI > 0.5).

Single-pulse activation of individual muscles was often selective, particularly for extrinsic hand muscles. Although the intrinsic muscles with similar functions (such as the lumbricales) were usually recruited together, the intrinsic muscles in different groups (thenar, interossei, and lumbral) were often recruited separately. On some electrodes (in elbow-level implants in the median nerve), the index lumbral was recruited alone, without activity on the other lumbricales, further indicating the specificity of muscle stimulation possible through intrafascicular electrodes. From previous work with intrafascicular electrodes, it is known that it is possible to evoke a response from only a portion of a fascicle. In the present study, it was not directly demonstrated whether the selectivity seen is principally due to a similar level of subfascicular selectivity or a more segregated set of fascicular bundles; however, the high impedance of the epineurium surrounding each fascicle substantially limits current spread from one fascicle to another. In either case, under the assumption that the nerve is musculotopically and somatotopically organized, current spread would cause physically close muscles and sensory areas to be activated together. Moreover, current spread cannot fully account for the musculotopy (or somatopy) observed here. Current spread from a given electrode to the neural tissue at an adjacent electrode might indeed active some fibers there, but such current spread could not fully explain why the dominant nEMG response at the given electrode was the same as that at the adjacent electrode. The strongest activation at the given site will reflect activation of the greatest number of nerve fibers, which probabilistically would occur in close proximity to the given electrode tip. Our data indicate that the selectivity of muscle activation was highly variable among different nerves and individuals. However, the overall musculotopic arrangement of fibers across the broad distribution of SIIs likely indicates that, independent of the degree to which the selectivity seen in this study is due to fasciculation or instead to subfascicular organization, there is a strong tendency for axons to particular muscles to group together, in agreement with other recent studies of nerve organization (Badia et al. 2010; Brill et al. 2009).

Pulse-train stimulation of selective electrodes generated smooth and distinct movements. Furthermore, different movements evoked by pulse-train stimulation were combined into functional grip-and-release sequences by activating several electrodes simultaneously or in sequence, and multiple types of grip (power, bucket, and pinch) could be reliably generated. These results all indicate the feasibility of using a penetrating electrode in the PNS as a prosthesis for limb reanimation in paralyzed patients. In the cat hindlimb, contractions produced by stimulation through multiple USEA electrodes that activate different motor units of the same muscles can be combined and interleaved to produce fatigue-resistant movements and stable static positions (Normann et al. 2005). So long as stimulation through the USEA electrodes can evoke responses in independent, nonoverlapping motor units, the same approach may work for monkey arm nerves, and presumably for human nerves as well. However, the time constraints of the present acute studies precluded systematic investigations of the overlap of USEA electrode responses and the effects of interleaved stimulation on fatigue resistance (see Normann et al. 2012 for details of the overlap and fatigability tests).

Studies of precision grip indicate that the intrinsic hand muscles, particularly the first dorsal interosseous and the muscles in the thenar group, are important for stabilizing the thumb and finger metacarpophalangeal (MCP) joints (Maier and Hepp-Reymond 1995). Unfortunately, present FES-based solutions do not fully access the hand muscles required for grasp, particularly the intrinsic hand muscles. Although direct stimulation of extrinsic hand muscles does provide functional power grip, the same intramuscular electrodes cannot easily be used for control of intrinsic hand muscles, largely because of their small size and the difficulty of surgical access. Because of these limitations, additional surgeries such as tendon transfers are sometimes necessary to achieve strong, stable grip force (Kilgore et al. 2008). In contrast, our three implanted USEAs allowed access to all the instrumented hand muscles, including all extrinsic and intrinsic muscles implicated in grip (Maier and Hepp-Reymond 1995; Schieber 1995). The activation of intrinsic and extrinsic hand muscles in a coordinated fashion allows for versatile hand posturing and gripping. Thus, for example, we were able to encode a stimulation sequence with four electrodes that brought the thumb and forefinger together (Supplemental Movie S3).

Stimulation of Sensory Fibers

Lack of sensory feedback is also a major challenge for users of a limb-replacement prosthesis. Without normal somatosensory feedback, many patients complain that their prosthetic limb is unwieldy and difficult to use (Biddiss and Chau 2007; Pezzin et al. 2004). Intrafascicular electrode arrays, such as the USEA, should be capable of selectively activating multiple, independent subsets of sensory fibers, just as they can for motor fibers. Motor and sensory nerves remain functional long after limb amputation, and stimulation of sensory fibers can elicit sensation (Anani et al. 1977; Dhillon et al. 2004; Dhillon and Horch 2005; Rossini et al. 2010; Warwick 2005). Hence, it may be possible to stimulate sensory fibers through USEAs and thereby evoke graded and varied sensory responses, including proprioception and pressure, to aid in gripping and reaching tasks.

Here, stimulation through individual USEA electrodes generated a variety of patterns of somatosensory cortical activation. In principle, such differentiable sensory signals could be used to provide cutaneous and proprioceptive sensory feedback from a neuroprosthetic artificial limb. Furthermore, the responses on a given cortical electrode were associated with stimulation on USEA electrodes that were also associated with specific muscles or classes of muscles (e.g., finger flexors). Because motor axons are organized musculotopically, and USEA electrodes that stimulate muscles with similar function are often near one another (e.g., Fig. 2B, FDP and FDS or FCR and PrT), we can conclude that the somatotopic and musculotopic maps in the nerve are in approximate register with one another. Because muscle activity could often be evoked on an electrode that also evoked sensory responses, it is likely that individual fascicles are mixed sensory-motor, consistent with previous studies (Chaudhuri et al. 2011; Schady et al. 1983).

The modality of sensory responses is difficult to determine from recordings from the cortical surface with the electrodes
used in this study, especially given that there is some overlap in the representation of body space in the cortex. However, activity from stretch receptors in a given muscle would be expected to lie in close proximity to motor fibers associated with the same muscle, indicating a high likelihood that the evoked potentials could convey some proprioceptive feedback for use in a prosthetic application. Such feedback might provide both intuitive, closed-loop prosthetic control and enhanced integration of the artificial limb with the user’s own internal body image.

Considerations for Long-Term Intrafascicular Electrode Implants

In SCI patients, the lower motoneurons remain mostly intact within the spinal cord. However, their chronic denervation can cause secondary degeneration, disassembly, or disorganization of the neuromuscular junction, changes in muscle excitability, and muscle atrophy. Thus, in a chronic implantation in a paralyzed individual, the initial conditions of the muscle and neuromuscular junction might be quite different from those in the intact animals in the present study. However, the initial peripheral changes that occur after SCI are largely reversible through FES, which, over time, can restore the neuromuscular junction’s natural arborization and can improve the efficacy of muscle activation (Baldi et al. 1998). Indeed, the ability to return the neuromuscular system toward its normal preinjury conditions may constitute an additional benefit of intraneural electrode technology. However, without early intervention SCI-induced hypertonia and spasticity can cause permanent changes to the functionality of muscles. All potential therapies, including the proposed USEA, PNS-based prosthesis, thus give the most benefit when provided immediately after injury.

Neurons may undergo important changes at the sites of chronic electrode implants that could affect electrode functionality. Fibrosis around electrodes and a continuing foreign body response can push axons away from the electrode tips, hampering their ability to record and stimulate neurons selectively (Biran et al. 2005). Although all neural implants face the problems associated with tissue response, central nervous system (CNS) implants of UEAs are subjected to less motion than nerve implants, and traditionally have been more reliable (Simeral et al. 2011) than long-term USEA implants in initial studies (Branner et al. 2004). However, recent and ongoing research has demonstrated substantive improvements in both long-term recording and stimulating capabilities of USEAs in cat sciatic nerve (Clark et al. 2011; Frankel et al. 2011; Ledbetter et al. 2011; Normann et al. 2012), which may translate to comparable success for USEAs in monkey arm nerves, and ultimately for clinical applications.

Issues of Muscle Control for the Design of the Motor Program

Strategies for motor restoration that are based on nerve stimulation explicitly involve the activation of lower motor neurons, which can engage spinal reflexes that can operate independently of the brain. For example, Renshaw reflexes involve negative feedback circuits in which a motoneuron inhibits itself (through a Renshaw interneuron). However, synaptic inhibition that occurs at the motoneuron soma many space constants away will have almost no effect on the direct activation of motor fiber axons at the USEA stimulation site. Because sensory and motor fibers are mixed within the nerve, activation of propriospinoceptive, cutaneous, or even nociceptive reflex pathways might be engaged coincidently with motor fiber stimulation in the awake animal. In principle, these effects might need to be incorporated into our artificial motor program. However, such considerations have not proven to be problematic in other clinical FES applications with extraneural stimulation. Given the high selectivity and relatively low currents (5–50 μA) associated with intraneural stimulation, these concerns also seem unlikely for USEAs.

Brain-Controlled Activation of Motor Nerve Fibers and Behavior

In a closely related project, we have demonstrated that recordings from similar UEAs implanted in the primary motor cortex of monkeys can provide accurate information about muscle activity during normal or intended movement (Pohlmeier et al. 2007). The information can be used to restore simple voluntary movement to monkeys during peripheral nerve block, used as a temporary paralysis model of SCI.

During this nerve-block paralysis, stimulation through intramuscular electrodes is used to evoke the intended movement, as inferred from the cortical recordings in real time (Ethier et al. 2012; Moritz et al. 2008; Pohlmeier et al. 2009). Potentially, in future work, USEA-based stimulation of motor fibers could be controlled in a similar manner, providing the monkey—and, ultimately, a paralyzed person—volitional control of more dexterous and coordinated hand movements than can be achieved with intramuscular or extraneural electrodes.
